ABSTRACT

Crowdsourced entity extraction is often used to acquire data for many applications, including recommendation systems, construction of aggregated listings and directories, and knowledge base construction. Current solutions focus on entity extraction using a single query, e.g., only using “give me another restaurant”, when assembling a list of all restaurants. Due to the time and cost of human labor, just focusing on a single query limits the practical applicability of these solutions.

In this paper, we leverage a *structured entity domain*, i.e., domains that can be fully described by a collection of attributes, each potentially displaying hierarchical structure. Given such an entity domain, we enable a richer space of queries, e.g., “give me another Moroccan restaurant in Manhattan that does takeout”. Naturally, enabling a richer space of queries comes with a host of issues, especially since many queries return empty answers. We develop new statistical tools that enable us to reason about the gain of issuing *additional queries* given little to no information, and show how we can exploit the overlaps across the results of queries for different points of the data domain to obtain accurate estimates of the gain. We cast the problem of *budgeted entity extraction* over large domains as an adaptive optimization problem that seeks to maximize the number of extracted entities, while minimizing the overall extraction costs. We evaluate our techniques with experiments on both synthetic and real-world datasets, demonstrating a yield of up to 3.3X over competing approaches for the same budget.

1. INTRODUCTION

Combining human computation with traditional computation, commonly referred to as *crowdsourcing*, has been recently proven beneficial in extracting knowledge and acquiring data for many application domains, including recommendation systems [2], knowledge base completion [17], entity extraction and structured data collection [24, 31]. In fact, extracting information, and entities in particular, from the crowd has been shown to provide access to more fine-grained information that may belong to the long tail of the web or even be completely unavailable on the web [9, 23, 34].

A fundamental challenge in crowdsourced entity extraction is reasoning about the completeness of the extracted information. More precisely, given a task that seeks to extract entities from a specific domain by asking human workers, e.g., “extract all restaurants in New York”, it is not easy to judge if we have extracted all entities (in this case restaurants). This is because we are in an “open world” [9] scenario.

Recent work [31] has considered the problem of crowdsourced entity extraction using a single type of *query* that is asked to humans; for our restaurant case, the query will be “give me another restaurant in New York”. That paper determines how many times

this query must be asked to different human workers before we are sure we have extracted all restaurants in New York. However, given the latency and monetary cost inherent in leveraging crowdsourcing, it is easy to see that just using this query repeatedly will not be practical for real-world applications, for two coupled reasons: (a) *wasted cost*: we will keep receiving the most popular restaurants and will have to wait a long while before we receive new or unseen restaurants (b) *lack of coverage*: beyond a point all the restaurants we get will already be present in our set of extracted entities — thus, for the less popular restaurants, we may never end up receiving them at all.

In this paper, our goal is to *make crowdsourced entity extraction practical*. To do so, we leverage a structured entity domain, i.e., a domain that can be fully described by a collection of attributes, each potentially displaying hierarchical structure. For example, in our restaurant case, we could have one attribute about location, one about cuisine, and one about whether the restaurant does takeout. We can then leverage this entity domain to use a much richer space of queries asked to human workers, considering all combinations of values for each of these attributes, e.g., “give me another Moroccan restaurant in Manhattan, New York, that does takeout”. In this manner, we can leverage these *specific, targeted queries* to extract not-so popular entities with attribute values set to specific ones, e.g., in this case, cuisine is “Moroccan”, location is “Manhattan”, and takeout is “Yes”.

If we view the structured data domain as a partially ordered set (poset), then each query can be mapped to a node in the graph describing its topology. Thus, our goal is to traverse the graph corresponding to the input poset by issuing queries corresponding to various nodes, often multiple times at each node. However, the poset describing the domain can be often large, leading to a host of additional challenges in deciding which queries to issue at any node: (a) *Sparsity*: Many of the nodes in the poset are likely to be empty, i.e., the queries corresponding to those nodes are likely to not have any answers; avoiding asking queries corresponding to these nodes is essential to keep monetary cost low. (b) *Interrelationships*: Many of the nodes in the poset are “coupled” with one another; for example, the results from a few queries corresponding to “give me another Moroccan restaurant in Manhattan, New York” can inform whether issuing queries corresponding to “give me another Moroccan restaurant in Manhattan, New York, that does takeout” is useful or not. We elaborate more on these challenges in Section 1.1 using examples from a real-world scenario.

Unfortunately, the techniques from Trushkowsky et al. [31] do not directly apply to the scenario where we are traversing a poset corresponding to this structured data domain, and new techniques are needed. To mitigate the shortcomings, one needs to tune the queries that are asked. However, deciding which queries to ask

among a large number of possible queries (exponential in the number of attributes describing the input domain) and when and how many times to ask each query, are both critical challenges that need to be addressed. Furthermore, unlike the main techniques proposed by Trushkowsky et al. [31], we focus on the budgeted case, where we are given a budget and we want to maximize the number of retrieved entities; we believe this is a more practical goal, instead of the goal of retrieving all entities. Our crowdsourced entity extraction techniques can be useful for a variety of applications that are naturally coupled to a structured entity domain, including:

- A newspaper that wants to collect a list of today’s events to be displayed on the events page every day. In this case, the structured data domain could include event type (e.g., music concerts vs. political rallies) or location, among other attributes.
- A stock trading firm wants to collect a list of stocks that have been mentioned by popular press on the previous day. In this case, the structured data domain could include stock type, popular press article type, or whether the mention was positive or negative, among other attributes.
- A real estate expert wants to curate a list of houses available for viewing today. The structured data domain in this case could include the price range, the number of floors, etc.
- A university wants to find all the faculty candidates on the job market. The structured data domain in this scenario includes the university of the applicant, specialization, and whether they are Ph.D./Postdoc.
- The PC chair of a new conference wants to find potential reviewers. The domain describing each of the candidates can be characterized by the university or company of the reviewer, expertise, qualifications, and so on.

1.1 A Real-World Scenario

To further exemplify the aforementioned challenges we review a large-scale real-world scenario where crowdsourcing is used to extract entities. We consider Eventbrite (www.eventbrite.com), an online event aggregator, that relies on crowdsourcing to compile a directory of events with detailed information about the location, type, date and category of each event. Typically, event aggregators are interested in collecting information about diverse events spanning from conferences and music festivals to political rallies across different location, i.e., countries or cities. In particular, Eventbrite collects information about events across different countries in the world. Each country is further split into cities and areas across the country. Moreover, events are organized according to their type and topic. We collected a dataset from Eventbrite spanning over 63 countries that are divided into 1,709 subareas (e.g., states) and 10,739 cities, containing events of 19 different types, such as rallies, tournaments, conferences, conventions, etc. and a time period of 31 days spanning over the months of October and November.

It is easy to see that two of the three dimensions, i.e., location and time, describing the domain of collected events are hierarchically structured. The overall domain can be fully specified if we consider the cross product across the possible values for location, event type and time. For each of the location, time, type dimensions we also consider a special *wildcard* value. Taking the cross-product across the possible values of these dimensions results in poset with a total of 8,508,160 nodes containing 57,805 distinct events overall. We point out that the events associated with a node in the poset overlap with the events corresponding to its descendants. First, we demonstrate how the sparsity challenge applies to Eventbrite.

EXAMPLE 1. We plot the number of events for each node in the

Figure 1: The attributes describing the events domain and the hierarchical structure of each attribute.

Figure 2: Pairwise overlaps for the 10 most populous nodes.

poset describing the event domain in the Eventbrite dataset. Out of 8,508,160 nodes only 175,068 nodes are associated with events while the remaining have zero events. Figure 1 shows the number of events per node (y-axis is in log-scale). As shown the most of the populated nodes have less than 100 events. Additionally, the most populated nodes of the domain correspond to nodes from the higher levels of the poset. When extracting events from such a sparse domain one needs to carefully decide on the crowdsourced queries to be issued especially if operating under a monetary budget.

As mentioned before, a critical challenge in such large domains is deciding on the queries to ask. However, the hierarchical structure of the data domain presents us with an opportunity. One approach would be to perform a top-down traversal of the poset and issue queries at the different nodes. Nevertheless, this gives rise to a series of challenges: (i) how can one decide on the number of queries to be asked at each node, (ii) when should one progress to deeper levels of the poset and (iii) which subareas should be explored. We elaborate on these in Section 2. Next, we focus on the second challenge, i.e., the interdependencies across poset nodes.

EXAMPLE 2. We consider again the Eventbrite dataset and plot the pairwise overlaps of the ten most populous nodes in the domain. Figure 2 shows the Jaccard index for the corresponding node pairs. As shown the event populations corresponding to these nodes overlap significantly. It is easy to see that when issuing queries at a certain domain node, we not only obtain events corresponding to this node but to other nodes in the domain as well.

A critical issue that stems from the overlaps across nodes is being able to decide how many answers to expect when issuing an additional query at a node whose underlying population overlaps with nodes associated with previous queries. In Section 2, we elaborate more on the dependencies across nodes of the poset.

1.2 Contributions

Motivated by the examples above, we study the problem of *budgeted crowd entity extraction over structured domains*. More precisely, we focus on domains described by a collection of attributes,

each following a known *hierarchical structure*, i.e., we assume that for each attribute the corresponding hierarchy is known.

We propose a novel algorithmic framework that exploits the structure of the domain to maximize the number of extracted entities under given budget constraints. In particular, we view the problem of entity extraction as a *multi-round adaptive optimization problem*. At each round we exploit the information on extracted entities obtained by previous queries to adaptively select the crowd query that will maximize the *gain* and cost trade-off at each round. The gain of a query is defined as the number of new unique entities extracted by it. We extend on previous query interfaces that considered only questions of the type “Give me k more entities from a domain” and examine *generalized queries* that can also include an *exclude list*. In general such queries are of the type “Give me k more entities that from a domain that are not in $\{A, B, \dots\}$ ”. Building upon techniques from the species estimation and the multi-armed bandits literature, we introduce a new methodology for estimating the gain for such generalized queries and show how the hierarchical structure of the domain can be exploited to improve the accuracy of our gain estimates. Our main contributions are as follows:

- We study the challenge of information flow across entity extraction queries for overlapping parts of the data domain.
- We formalize the notion of an exclude list for crowdsourced entity extraction queries and show how previously proposed gain estimators can be extended to handle such queries.
- We develop a new technique to estimate the gain of generalized entity extraction queries under the presence of dependent information. The proposed technique exploits the structure of the data domain to obtain accurate estimates.
- We introduce an adaptive optimization algorithm that takes as input the gain estimates for different types of queries and identifies querying policies that maximize the total number of retrieved entities under given budget constraints.
- Finally, we show that our techniques can effectively solve the problem of budgeted crowd entity extraction for large data domains on both real-world and synthetic data.

2. PRELIMINARIES

In this section we first describe our structured data domain, then describe entities and entity extraction queries or interfaces, along with the response and cost model for these queries. Then we focus on crowdsourced entity extraction using these interfaces and consider the problem of maximizing the number of extracted entities. In particular, we define the problem of *crowd entity extraction over structured domains* under budget constraints. Then, we formally introduce the challenge of dependencies across queries when extracting entities from structured domains, and finally, we present an overview of our proposed algorithmic framework.

2.1 Structured Data Domain

Let \mathcal{D} be a data domain described by a set of discrete attributes $\mathcal{A}_D = \{A_1, A_2, \dots, A_d\}$. Let $\text{dom}(A_i)$ denote the domain of each attribute $A_i \in \mathcal{A}_D$. We focus on domains where each attribute A_i is hierarchically organized. For example, consider the Eventbrite domain introduced in Section 1.1. The data domain \mathcal{D} corresponds to all events and the attributes describing the entities in \mathcal{D} are $\mathcal{A}_D = \{\text{“Event Type”}, \text{“Location”}, \text{“Date”}\}$. Figure 3 shows the hierarchical organization of each attribute.

The domain \mathcal{D} can be viewed as a *poset*, i.e., a partially ordered set, corresponding to the cross-product of all available hierarchies¹.

¹Note that \mathcal{D} is not a lattice since there is no unique infimum.

Eventbrite Event Data Domain

Figure 3: The attributes describing the Eventbrite domain and the hierarchical structure of each attribute.

Part of the poset corresponding to the previous example is shown in Figure 4. We denote this cross-product as \mathcal{H}_D . As can be seen in Figure 4, there are nodes, such as $\{\}$, where no attributes are specified, and nodes, such as $\{X1\}$ and $\{C1\}$ where just one of the attribute values is specified, as well as nodes, such as $\{X2, ST2\}$, where multiple attribute values are specified.

Figure 4: Part of the poset defining the entire event entity domain described by the attributes in Figure 3.

2.2 Entities and Entity Extraction Queries

Entities. Our goal is to extract entities that belong to the domain \mathcal{D} . We assume that each entity e can be uniquely associated with one of the leaf nodes in the hierarchy \mathcal{H}_D ; that is, there is a unique set of “most-specific” values of A_1, \dots, A_d for every entity. For example, in our Eventbrite dataset, each entity (here, a local event) takes place in a specific city, and on a specific day. Our techniques also work for the case when entities can be associated only with “higher level” nodes, but we focus on the former case for simplicity.

Queries. Next, we describe queries for extracting entities from the crowd. First, a query q is issued at a node $v \in \mathcal{H}_D$; that is, a query specifies zero or more attribute values from A_1, \dots, A_d that are derived from the corresponding values of v , implicitly requiring the worker to find entities that match the specified attribute values.

Given a query issued at a node, there are three different configurations one can use to extract entities from the crowd: The first configuration corresponds to *single entity queries* where workers are required to provide “one more” entity that match the specified attribute values mentioned in the query. Considering the Eventbrite example introduced in the previous section, an example of a single entity query would be asking a worker to provide “a concert in Manhattan, New York”. The second configuration corresponds to *queries of size k* where workers are asked to provide up to k distinct entities. Finally, the last configuration corresponds to *exclude list queries*. Here, workers are additionally provided with l entities that have already been extracted and are required to provide up to k distinct entities under the constraint that none of them is included in this exclude list of size l . It is easy to see that the last configuration generalizes the previous two. Therefore, in the remainder of the paper, we will only consider queries using the third configuration. To describe a query, we will use the notation $q(k, l)$ denoting a query of size k accompanied with an exclude list of length l .

Query Response. Given a query $q(k, l)$ issued at a node $v \in \mathcal{H}_D$, with an exclude list of entities S , $|S| = l$, a human worker gives us k distinct entities that belong to the domain \mathcal{D} , match the specified attribute values mentioned in the query (derived from v), and are not present in S . Furthermore, the human worker provides us the information for the attributes that are not specified in q for each of the k entities. For example, if our query is “a concert in Manhattan, New York”, with $k = 1, l = 0$, the human worker gives us one concert in Manhattan, New York, but also gives us the day on which the concert will take place (here, the missing, unspecified attribute). If the query is “a concert in the US”, with $k = 1, l = 0$, the human worker gives us one concert in the US, but also gives the day on which the concert will take place, as well as the specific city. If less than k entities are present in the underlying population, workers have the flexibility to report either an empty answer or a smaller number of entities (Section 3.4).

While the reader may wonder if getting additional attributes for entities is necessary, note that this information allows us to reason about which all nodes in \mathcal{H}_D the entity belongs to; without this, it is impossible to effectively traverse the poset. Furthermore, we find that in most practical applications, it is useful to get the values of the missing attributes in order to organize and categorize the extracted entities better.

Notice also that we assume that human workers specify or extract an entity correctly (e.g., no abbreviations, typos, and so on), once again for simplicity. It is straightforward to use an entity resolution or string matching (e.g., jaccard coefficient) algorithm to group identical entities together. Furthermore, since we are getting all attributes for each entity, we can use these attributes to further ascertain similarity of entities. In our experiments on real datasets, we found that there were no cases where humans introduced errors to the attribute values of extracted entities. Only minor errors (e.g., misspelled entity names) were detected.

Query Cost. In a typical crowdsourcing marketplace, tasks have different costs depending on their difficulty. Thus, crowdsourced queries of different difficulties should also exhibit different costs. Let $c(\cdot)$ be a cost function for any query $q(k, l)$. This cost function should obey the following properties: (a) given a query with a fixed query size its cost should increase as the size of its exclude list is increasing, and (b) given a query with a fixed exclude list size its cost should increase as the number of requested answer increases. These are fixed upfront by the interface designer based on the amount of work involved.

2.3 Crowdsourced Entity Extraction

The basic version of *crowdsourced entity extraction* [31] seeks to extract entities that belong to \mathcal{D} , by simply using repeated queries at the root node, with $k = 1, l = 0$ (subsequent versions relax l to be non-zero). However, when considering large entity domains, such as the event domain, one may need to issue a series of entity extraction queries at multiple nodes in \mathcal{H}_D — often overlapping with each other — so that the entire domain is covered. Issuing queries at different nodes ensures that the coverage across the domain will be maximized.

We let π denote a *querying policy*, that is, a chain of queries at different nodes in \mathcal{H}_D . Notice that multiple queries can be issued at the same node. Let $C(\pi)$ denote the overall cost, in terms of monetary cost (or equivalently, latency, since the more queries are issued, the more time the policy will take) of a querying policy π . We define the gain of a querying policy π as the total number of unique entities, denoted by $\mathcal{E}(\pi)$ extracted when following policy π . Thus, there is a natural tradeoff between the gain (i.e., the number of extracted entities) and the cost of policies.

Here, we require that the user will *only* provide a monetary budget τ_c imposing a constraint on the total cost of a selected querying policy, and optimize over all possible querying policies across different nodes of \mathcal{H}_D . Our goal is to identify the policy that maximizes the number of retrieved entities under the given budget constraint. More formally, we define the problem of budgeted crowd entity extraction as follows:

PROBLEM 1 (BUDGETED CROWD ENTITY EXTRACTION). *Let \mathcal{D} be a given entity domain and τ_c a monetary budget on the total cost of issued queries. The Budgeted Crowd Entity Extraction problem seeks to find a querying policy π_S^* using queries over nodes in \mathcal{H}_D that maximizes the number of unique entities extracted $\mathcal{E}(\pi_S^*)$ under the constraint $C(\pi_S^*) \leq \tau_c$.*

Notice that due to the different query configurations, the optimal querying policy for budgeted crowd entity extraction should also identify the optimal configuration (k, l) for each query in π_S^* .

The cost of a querying policy π is defined as the total cost of all queries issued by following π . We have that $C(\pi) = \sum_{q \in \pi} c(q)$ where the cost of each query q is defined according to a cost model specified by the user. Computing the total cost of a policy π is easy. However, the gain $\mathcal{E}(\pi)$ of a policy π is unknown as we do not know in advance the entities corresponding to each node in \mathcal{H}_D , and hence, needs to be estimated, as we discuss next.

2.4 Underlying Query Response Model

In order to reason about the occurrence of entities as response to specific queries, we need an underlying query response model. Our query response model is based on the notion of popularity.

Popularities. We assume that each underlying entity has a *fixed, unknown popularity value* with respect to crowd workers. Given a query $q(1, 0)$, asking for one entity and using an exclude list of size 0, the probability that we will get entity e that satisfies the constraints specified by q is nothing but the popularity value of e divided by the popularity value of all entities e' that also satisfy the constraints in q . As an example, if there are only two entities e_1, e_2 that satisfy the constraints specified by a given query q_1 , with popularity values 3 and 2, then the probability that we get e_1 on issuing a query $q_1(1, 0)$ is $3/5$. If an exclude list S is specified, then the probability that we will get an entity $e \notin S$ is the popularity value of e divided by the popularity values of all entities $e' \notin S$ also satisfying the constraints specified by q . Note that, we do not assume that all workers follow the same popularity distribution. Rather the overall popularity distribution can be seen as an average of the popularity distributions across all workers.

Thus, since workers are asked to provide a limited number of entities as response to a query, each entity extraction query can be viewed as taking a random sample from an unknown population of entities. In the rest of the paper, we will refer to the distribution characterizing the popularities of entities in a population of entities as the *popularity distribution* of the population. We note that this is equivalent to the underlying assumption in the species estimation literature [6] (Section 3).

Then, estimating the gain of a query $q(k, l)$ at a node $v \in \mathcal{H}_D$ is equivalent to estimating the number of new entities extracted by taking additional samples from the population of v given all the retrieved entities by past samples associated with node v [31].

Samples for a Node. When extracting entities, the retrieved entities for a node v can correspond to two different kinds of samples: (i) those that were extracted by considering the **entire population** corresponding to node v (ii) and those that we obtained by sampling **only a part of the population** corresponding to v . Samples

for a node v can be obtained either by querying node v or by indirect information flowing to v by queries at other nodes. We refer to the latter case as *dependencies across queries*.

Figure 5: An example query that extract an entity sample from the red node. The nodes marked with green correspond to the nodes for which indirect entity samples are retrieved.

We use an example considering the poset in Figure 4, to illustrate these two cases. The example is shown in Figure 5. Assume a query $q(k, 0)$ issued against node $\{\text{EventType X1}\}$. Assume that the query result contains entities that correspond only to node $\{\text{X1, ST2}\}$. The green nodes in Figure 5 are nodes for which samples are obtained indirectly without querying them. Notice, that all these nodes are ancestors of $\{\text{X1, ST2}\}$. Analyzing the samples for the different nodes we have:

- The samples corresponding to nodes $\{\text{X1, C1}\}$ and $\{\text{X1, ST2}\}$ were obtained by considering their *entire population*. The reason is that node $\{\text{EventType X1}\}$ is an ancestor of both and the entity population corresponding to it fully contains the populations of both $\{\text{X1, C1}\}$ and $\{\text{X1, ST1}\}$.
- The samples corresponding to nodes $\{\}$, $\{\text{Country C1}\}$ and $\{\text{State ST2}\}$ were obtained by considering only part of their population. The reason is that the population of node $\{\text{EventType X1}\}$ does not fully contain the populations of these nodes.

Samples belonging to both types need to be considered when estimating the gain of a query at a node $v \in \mathcal{H}_D$. To address this issue we merge the extracted entities for each node in \mathcal{H}_D into a single sample and treat the unified sample as being extracted from the entire underlying population of the node. As we discuss later in Section 4 we develop querying strategies that traverse the poset \mathcal{H}_D in a top-down approach, hence, the number of samples belonging in the first category, i.e., samples retrieved considering the entire population of a node, dominates the number of samples retrieved by considering only part of a node’s population. Moreover, it has been shown by Hortal et al. [12] that several of the techniques that can be used to estimate the gain of a query (see Section 3) are insensitive to differences in the way the samples are aggregated.

2.5 Framework Overview

We present an overview of our proposed framework for solving the problem of budgeted crowd entity extraction over structured domains. We view the optimization problem described in Section 2.3 as a multi-round adaptive optimization problem where at each round we solve the following subproblems:

- **Estimating the Gain for a Query.** For each node in $v \in \mathcal{H}_D$, consider the retrieved entities associated with v and estimate the number of new unique entities that will be retrieved if a new query $q(k, l)$ is issued at v . This needs to be repeated for all possible configurations of k and l .
- **Detecting the Optimal Querying Policy.** Using the gain estimates from the previous problem as input, identify the next

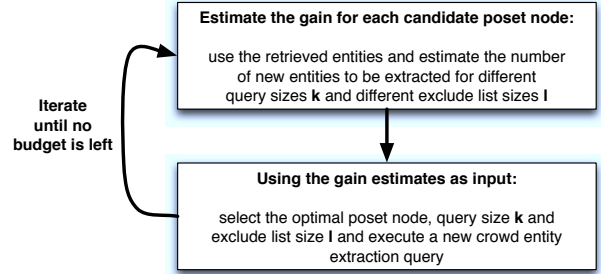

Figure 6: Framework overview for budgeted entity extraction.

(query, node) combination so that the total gain across all rounds is maximized with respect to the given budget constraint.

Our proposed framework iteratively solves the aforementioned problems until the entire budget is used. Figure 6 shows a high-level diagram of our proposed framework.

3. ESTIMATING THE GAIN OF QUERIES

We now present a novel estimation technique for the return of a generalized query $q(k, l)$ at a node $v \in \mathcal{H}_D$. Previous work [31] has drawn connections between this problem and species estimation literature [6]. However, these techniques are agnostic to any structure exhibited by the domain under consideration and to the presence of an exclude-list-based query interface. In particular, there is no mechanism for estimating the number of new tuples extracted by a query when restricting the worker answer to not contain any entities from a certain collection of entities as enforced by an exclude list. We first review the existing methodology for estimating the gain of a query, then we discuss how these estimators can be extended to consider an exclude list, and finally, we present a new methodology for estimating the gain of generalized queries $q(k, l)$.

3.1 Previous Estimators

Consider a specific node $v \in \mathcal{H}_D$. Prior work only considers samples retrieved from the entire population associated with v and does not consider an exclude list. Let Q be the set of all existing samples retrieved by issuing queries against v without an exclude list. These samples can be combined into a single sample of size $n = \sum_{q \in Q} \text{size}(q)$. Let f_i denote the number of entities that appear i times in this unified sample, and let f_0 denote the number of unseen entities from the population under consideration. Finally, let C be the population coverage of the unified sample — that is, this is the fraction of the population covered by the sample.

A new query $q(k, 0)$ at node v can be viewed as increasing the size of the unified sample by k . Prior work used techniques from species estimation to estimate the expected number of new entities returned in $q(k, 0)$. Shen et al. [27], derive an estimator for the number of new species \hat{N}_{Shen} that would be found in an increased sample of size k . The approach assumes that the unobserved entities have equal relative popularity. An estimate of the unique elements found in an increased sample of size k is given by:

$$\hat{N}_{Shen} = f_0 \left(1 - \left(1 - \frac{1 - C}{f_0} \right)^k \right) \quad (1)$$

At a high-level, the second term of Shen’s formula corresponds to the probability that at least one unseen entity will be present in a query asking for k more entities. Thus, multiplying this quantity with the number of unseen entities f_0 corresponds to the expected number of unseen entities that will be present in the result of a new query $q(k, 0)$.

Notice, that the quantities f_0 and C are unknown and thus need to be estimated considering the entities in the running unified sample. The coverage can be estimated by considering the Good-Turing estimator $\hat{C} = 1 - \frac{f_1}{n}$ for the existing retrieved sample. On the other hand, multiple estimators have been proposed for estimating the number of unseen entities f_0 . Trushkowsky et al. [31] proposed a variation of an estimator introduced by Chao et al. [6] to estimate f_0 . Nevertheless, the authors argue that the original estimator proposed by Chao performs similarly with their approach when estimating the gain of an additional query $q(k, 0)$.

The estimator by Chao [6] on which the authors build has been shown to result in considerable bias in cases where the number of observed entities from a population represents only a *small fraction* of the entire population [13]. Notice, that this assumption holds for crowdsourced entity extraction in a large domain, i.e., we are observing only a small portion of the entire population. To address this problem, Hwang and Shen [13] proposed a regression based technique to estimate f_0 . This estimator is shown to result in significantly smaller bias and empirically outperforms previously proposed estimators, including the one proposed by Chao, when the ratio of retrieved entities to the entire entity population is small. It also performs comparably to previous estimators when the ratio is larger. Notice that the output of this estimator can also be used as a plug-in quantity in Equation (1).

However, both the aforementioned estimators are agnostic to an exclude list. Next, we discuss how one can estimate the return of a query $q(k, l)$ in the presence of an exclude list of size l .

3.2 Queries With an Exclude List

Consider an exclude list of size l . As discussed before an exclude list is a set of entities that correspond to invalid worker answers. Considering an exclude list for a query at a node $v \in \mathcal{H}_D$ corresponds to limiting our sampling to a restricted subset of the entity population corresponding to node v . In fact, we want to estimate the expected return of a query of size k conditioning on the fact that the entities in the exclude list will not be retrieved by any new sample. The latter corresponds to removing these entities from the population under consideration. Thus, the estimates \hat{f}_0 and \hat{C} should be updated before applying Equation (1) to compute the expected return of a query of size k . This can be done by removing the entities included in the exclude list from the running sample for node v , recomputing the entity counts f_i and following the techniques presented above for computing the updated estimates for \hat{f}_0 and \hat{C} . This approach requires that the exclude list is known in advance. To construct an exclude list one can follow a randomized approach, where l of the retrieved entities are including in the list uniformly at random. The generated list can be used to update the frequency counts f_i and estimate the gain of the query. Bootstrapping can also be used to obtain improved estimates.

3.3 Regression Based Gain Estimation

Building upon the approach of Hwang and Shen [13], we introduce a new technique for estimating the gain of a generalized query $q(k, l)$ directly without using the estimator shown in Equation (1). Since we want to estimate the gain even for nodes with a small number of retrieved entities we propose a regression based technique that is able to capture the structural properties of the expected gain function as discussed below.

To derive the new estimator we make use of the generalized jackknife procedure for species richness estimation [11]. Given two (biased) estimators of S , say \hat{S}_1 and \hat{S}_2 , let R be the ratio of

their biases:

$$R = \frac{E(\hat{S}_1) - S}{E(\hat{S}_2) - S} \quad (2)$$

By the generalized jackknife procedure, we can completely eliminate the bias resulting from either \hat{S}_1 or \hat{S}_2 via

$$S = G(\hat{S}_1, \hat{S}_2) = \frac{\hat{S}_1 - R\hat{S}_2}{1 - R} \quad (3)$$

provided the ratio of biases R is known. However, R is unknown and needs to be estimated.

Let D_n denote the number of unique entities in a unified sample of size n . We consider the following two biased estimators of S : $\hat{S}_1 = D_n$ and $\hat{S}_2 = \sum_{j=1}^n D_{n-1}(j)/n = D_n - f_1/n$ where $D_{n-1}(j)$ is the number of species discovered with the j th observation removed from the original sample. Replacing these estimators in Equation (3) gives us:

$$S = D_n + \frac{R}{1 - R} \frac{f_1}{n} \quad (4)$$

Similarly, for a sample of increased size $n + m$ we have:

$$S = D_{n+m} + \frac{R'}{1 - R'} \frac{f'_1}{n + m} \quad (5)$$

where R' is the ratio of the biases and f'_1 the number of singleton entities for the increased sample. Let $K = \frac{R}{1 - R}$ and $K' = \frac{R'}{1 - R'}$. Taking the difference of the previous two equations we have:

$$D_{n+m} - D_n = K \frac{f_1}{n} - K' \frac{f'_1}{n + m} \quad (6)$$

Therefore, we have:

$$new = K \frac{f_1}{n} - K' \frac{f'_1}{n + m} \quad (7)$$

We need to estimate K , K' and f'_1 . We start with f'_1 , which denotes the number of singleton in the increased sample of size $n + m$. Notice, that f'_1 is not known since we have not obtained the increased sample yet, so we need to express it in terms of f_1 , i.e., the number of singletons, in the running sample of size n . We have:

$$f'_1 = new + f_1 - f_1 * \Pr[\text{in query of size } m] \quad (8)$$

Following an approach similar to Shen et al. [27], we have that the probability of a singleton appearing in a query of size m is:

$$\Pr[\text{in query of size } m] = \sum_{k=0}^m (1 - (1 - \frac{1}{f_1})^k) \binom{m}{k} (1 - p_1)^k p_1^{m-k} \quad (9)$$

where p_1 denotes the probability that a singleton item in the sample of size n will be selected in a future query. We estimate this probability using the corresponding Good-Turing estimator considering the running sample. We have:

$$p_1 = \hat{\theta}(1) = \frac{1}{n} 2 \frac{N_2}{N_1} \quad (10)$$

where N_2 is the number of entities that appear twice in the sample and N_1 is the number of singletons. Eventually we have that:

$$f'_1 = new + f_1 (1 - \sum_{k=0}^m (1 - (1 - \frac{1}{f_1})^k) \binom{m}{k} (1 - p_1)^k p_1^{m-k}) \quad (11)$$

Replacing the last equation in Equation (7) we have:

$$\begin{aligned} new &= K \frac{f_1}{n} - K' \frac{new + f_1(1-P)}{n+m} \\ new &= \frac{1}{(1 + \frac{K'}{n+m})} (K \frac{f_1}{n} - K' \frac{f_1(1-P)}{n+m}) \end{aligned}$$

Next, we discuss how one can estimate K and K' . To estimate K we follow the regression approach introduced by Hwang and Shen [13]. From the Cauchy-Schwarz inequality we have that:

$$K = \frac{\sum_{i=1}^S (1-p_i)^n}{\sum_{i=1}^S p_i (1-p_i)^{n-1}} \geq \frac{(n-1)f_1}{2f_2} \quad (12)$$

This can be generalized to:

$$K = \frac{nf_0}{f_1} \geq \frac{(n-1)f_1}{2f_2} \geq \frac{(n-2)f_2}{3f_3} \geq \dots \quad (13)$$

Let $g(i) = \frac{(n-i)f_i}{(i+1)f_{i+1}}$. From the above we have that the function $g(x)$ is a smooth monotone function for all $x \geq 0$. Moreover, let y_i denote a realization of $g(i)$ mixed with a random error. Hwang and Shen how one can use an exponential regression model to estimate K . The proposed model corresponds to:

$$y_i = \beta_0 \exp(\beta_1 i^{\beta_2}) + \epsilon_i \quad (14)$$

where $i = 1, \dots, n-1$, $\beta_0 > 0$, $\beta_1 < 0$, $\beta_2 > 0$ and ϵ_i denotes random errors. It follows that $K = \beta_0$.

Finally, we show how one can estimate the value of K' for an increased sample of size $n+m$. First, we show that K increases monotonically as the size of the running sample increases. Let $K(n) = \frac{\sum_{i=1}^S (1-p_i)^n}{\sum_{i=1}^S p_i (1-p_i)^{n-1}}$ be a function returning the value of K for a sample of size n . We have the following lemma.

LEMMA 1. We have $K(n+m) \geq K(n)$, $\forall n, m > 0$.

PROOF. In the remainder of the proof we will denote $K(n+m)$ as K' . By definition we have that $K = \frac{\sum_{i=1}^S (1-p_i)^n}{\sum_{i=1}^S p_i (1-p_i)^{n-1}}$ and $K' = \frac{\sum_{i=1}^S (1-p_i)^{n+m}}{\sum_{i=1}^S p_i (1-p_i)^{n+m-1}}$. We want to show that:

$$\begin{aligned} \frac{\sum_{i=1}^S (1-p_i)^{n+m}}{\sum_{i=1}^S p_i (1-p_i)^{n+m-1}} &\geq \frac{\sum_{i=1}^S (1-p_i)^n}{\sum_{i=1}^S p_i (1-p_i)^{n-1}} \\ \sum_{i=1}^S (1-p_i)^{n+m} \sum_{j=1}^S p_j (1-p_j)^{n-1} &\geq \sum_{i=1}^S p_i (1-p_i)^{n+m-1} \sum_{j=1}^S (1-p_j)^n \\ \sum_{i,j:i < j} [(1-p_i)^{n+m} p_j (1-p_j)^{n-1} - p_i (1-p_i)^{n+m-1} (1-p_j)^n] &+ (1-p_j)^{n+m} p_i (1-p_i)^{n-1} - p_j (1-p_j)^{n+m-1} (1-p_i)^n \geq 0 \\ \sum_{i,j:i < j} [(1-p_i)^{n-1} (1-p_j)^{n-1} (p_j - p_i) ((1-p_i)^m - (1-p_j)^m)] &\geq 0 \end{aligned} \quad (15)$$

But the last inequality always holds since each term of the summation is positive. In particular, if $p_j \geq p_i$ then also $1-p_i \geq 1-p_j$ and if $p_j \leq p_i$ then $1-p_i \leq 1-p_j$. \square

We have that $K(n)$ is an increasing function of the sample size. Moreover, $K(n)$ has a decreasing slope. We model K as a generalized logistic function of the form $f(x) = \frac{A}{1+e^{xp(-G(x-D))}}$. As we observe samples of different sizes for different queries we estimate K as described above and therefore we observe different realizations of $f(\cdot)$. Thus, we can learn the parameters of f and use it to estimate K' . In the presence of an exclude list of size l we follow the approach described in Section 3.2 to update the quantities f_i used in the analysis above.

3.4 Negative Answers and Gain Estimation

Next, we study the effect of *negative answers* on estimating the gain of future queries. It is possible to issue a query at a specific node $v \in \mathcal{H}_D$ and receive no entities, i.e., we receive a negative answer. This is an indication that the underlying entity population of v is empty. In such a scenario, we assign the expected gain of future queries at v and all its descendants to zero.

Another type of negative answer corresponds to the scenario where we issue a query at an ancestor node u of v and receive no entities associated with v but received some entities for u . Notice, that in this case, we do not have enough information to update our estimates for node u . The reason is that due to the restricted query size entities from other descendants of u may be more popular with respect to the popularity distribution of u .

4. DISCOVERING QUERYING POLICIES

In this section, we focus on the second component of our proposed algorithmic framework. Specifically, we introduce a querying strategy based on a multi-round adaptive optimization algorithm to maximize the total gain across all rounds under the given budget constraints. The algorithmic framework we propose builds upon ideas from the multi-armed bandit literature [4, 8]. In particular, at each round, the proposed algorithm uses as input the estimated gain or return for queries $q(k, l)$ at the different nodes in \mathcal{H}_D . Before presenting our proposed algorithm we list several challenges associated with this adaptive optimization problem.

- The first challenge is that the number of nodes in \mathcal{H}_D is exponential with respect to the number of attributes \mathcal{A}_D describing the domain of interest. Querying every possible node to estimate its expected return for different queries $q(k, l)$ is prohibitively expensive. That said, typical budgets do not allow algorithms to query all nodes in the hierarchy, so this intractability may not hurt us all that much. For example, we can keep estimates for each of the nodes for which at least one entity has been retrieved.
- The second challenge is balancing the tradeoff between *exploitation* and *exploration* [4]. The first refers to querying nodes for which sufficient entities have been retrieved and hence we have an accurate estimate for their expected return; the latter refers to exploring new nodes in \mathcal{H}_D to avoid locally optimal policies.

4.1 Balancing Exploration and Exploitation

While issuing different queries $q(k, l)$ at different nodes of \mathcal{H}_D we obtain a collection of entities that can be assigned to different nodes in \mathcal{H}_D . For each node we can estimate the return of a new query $q(k, l)$ using the estimator presented in Section 3.3. However, this estimate is based on a rather small sample of the underlying population. Thus, exploiting this information at every round may need to suboptimal decision. This is the reason why one needs to balance the trade-off between exploiting nodes for which the estimated return is high and nodes that haven't been queried many times. Formally, the latter corresponds to upper-bounding the expected return of each potential action with a confidence interval that depends on both the variance of the expected return and the number of times an action is evaluated.

Let $r(\alpha)$ denote the expected return of action α that is an estimate of the true return $r^*(\alpha)$. Moreover, let $\sigma(\alpha)$ be an error component on the return of action α chosen such that $r(\alpha) - \sigma(\alpha) \leq r^*(\alpha) \leq r(\alpha) + \sigma(\alpha)$ with high probability. The parameter $\sigma(\alpha)$ should take into account both the empirical variance of the expected return as well as our uncertainty if an action or similar actions (e.g., with different k, l but at the same node) has been chosen few times.

Let $n_{\alpha,t}$ be the number of times we have chosen action α by round t , and let $v_{\alpha,t}$ denote the maximum value between some constant c (e.g., $c = 0.01$) and the empirical variance for action α at round t . The latter can be computed using bootstrapping over the retrieved sample and applying the estimators presented in Section 3.3 over these bootstrapped samples. Several techniques have been proposed in the multi-armed bandits literature to compute the parameter $\sigma(\alpha)$ [30]. Teytaud et al. [30] showed that techniques considering both the variance and the number of times an action has been chosen tend to outperform other proposed methods. Based on this observation, we choose to use the following formula for sigma:

$$\sigma(\alpha) = \sqrt{\frac{v_{\alpha,t} \cdot \log(t)}{n_{\alpha,t}}} \quad (16)$$

4.2 A Multi-Round Querying Policy Algorithm

We now introduce our proposed multi-round algorithm for solving the budgeted entity enumeration problem. At a high-level, our algorithm proceeds as follows: Let \mathcal{S} denote the set of all potential queries $q(k, l)$ that can be issued at the different nodes of \mathcal{H}_D during a round r . Moreover, let $r(\alpha) + \sigma(\alpha)$ and $c(\alpha)$ be the upper-bounded return (i.e., gain) and cost for an action $\alpha \in \mathcal{S}$. At each round the algorithm identifies an action in \mathcal{S} that maximizes the quantity $\frac{r(\alpha) + \sigma(\alpha)}{c(\alpha)}$ under the constraint that the cost of action α is less or equal to the remaining budget. Since we are operating under a specified budget one can view the problem in hand as a variation of the typical knapsack problem. If no such action exists then the algorithm terminates. Otherwise the algorithm issues the query corresponding to action α , updates the set of unique entities obtained from the queries, the remaining budget and updates the set of potential queries $q(k, l)$ that can be executed in the next round. An overview of the proposed algorithm is shown in Algorithm 1.

As discussed before, the size of \mathcal{H}_D is exponential to the values of attributes describing it, and thus, considering all the possible queries corresponding to the different nodes of the hierarchy can be prohibitively expensive. Next, we discuss how one can initialize and update the set of potential actions as the algorithm progresses considering the structure of the poset \mathcal{H}_D and the retrieved entities from previous rounds.

Algorithm 1 Overall Algorithm

```

1: Input:  $\mathcal{H}_D$ : the hierarchy describing the entity domain;  $r, \sigma$ : value oracle access to gain upper bound;  $c$ : value oracle access to the query costs;  $\beta_c$ : query budget;
2: Output:  $\mathcal{E}$ : a set of extracted distinct entities;
3:  $\mathcal{E} \leftarrow \{\}$ 
4:  $RB \leftarrow \beta_c$  /* Initialize remaining budget */
5:  $\mathcal{S} \leftarrow \text{UpdateActionSet}(\mathcal{H}_D)$ 
6: while  $RB > 0$  and  $\mathcal{S} \neq \{\}$  do
7:    $\alpha \leftarrow \arg \max_{\alpha \in \mathcal{S}} \frac{r(\alpha) + \sigma(\alpha)}{c(\alpha)}$  such that  $RB - c(\alpha) > 0$ 
8:   if  $\alpha$  is NULL then
9:     break;
10:   $RB \leftarrow RB - c(\alpha)$  /* Update budget */
11:  Issue query corresponding to  $\alpha$ 
12:   $E \leftarrow$  entities from query
13:   $\mathcal{E} \leftarrow \mathcal{E} \cup E$  /* Update unique entities */
14:   $\mathcal{S} \leftarrow \text{UpdateActionSet}(\mathcal{H}_D)$ 
15: return  $\mathcal{E}$ 

```

4.3 Updating the Set of Actions

Due to the exponential size of the poset \mathcal{H}_D , we need to limit the set of possible actions Algorithm 1 considers. To avoid keeping estimates for actions with bad returns we exploit the structure the

given domain \mathcal{H}_D . We propose an algorithm that updates the set of actions by traversing the input poset in a top-down manner extending it by adding new actions that corresponds to queries for nodes that are *direct descendants* of already queried nodes.

The intuition behind this approach is the following. It is easy to see that due to the hierarchical structure of the poset nodes at higher levels of the poset corresponds to larger populations of entities. Therefore, issuing queries at these nodes can potentially result to a larger number of extracted entities. Also, traversing the poset in a bottom-down fashion allows one to detect sparsely populated areas of the poset and hence avoid spending any of the available budget on issuing queries corresponding to them.

In more detail, our approach for updating the set of available actions (Algorithm 2) proceeds as follows: If the set of available actions is empty start by considering all possible queries that can be issued at the root of \mathcal{H}_D (Ln. 4-5). The set of possible queries corresponds to queries $q(k, l)$ for all combinations of the values of parameters k and l . Recall that these are pre-specified by the designer of the querying interface. If the set of available actions is not empty, we consider the node associated with the action selected in the last round and populate the set of available actions with all the queries corresponding to its direct descendants (Ln. 7-9). As mentioned above the number of nodes in \mathcal{H}_D can be prohibitively large, therefore we also remove any *bad actions* from the running set of actions (Ln. 10-14). An action α is bad when $r(\alpha) + \sigma(\alpha) < \max_{\alpha' \in \mathcal{S}} (r(\alpha') - \sigma(\alpha'))$. Intuitively, this inequality states that we do not need to consider again an action as long as there exists another action such that the upper-bounded return of the former is lower than the lower bounded return of the latter. This is a standard technique adopted in multi-armed bandits to limit the number of actions considered by the algorithm [8].

Algorithm 2 UpdateActionSet

```

1: Input:  $\mathcal{H}_D$ : the hierarchy describing the entity domain;  $u$ : a node in  $\mathcal{H}_D$  associated with the last selected action;  $\mathcal{S}_{old}$ : the running set of actions;  $V_k$ : set of values for query parameter  $k$ ;  $V_l$ : set of values for query parameter  $l$ ;
2: Output:  $\mathcal{S}_{new}$ : the updated set of actions;
3: /* Extend Set of Actions */
4: if  $\mathcal{S}_{old}$  is empty then
5:   return {Root of  $\mathcal{H}_D$ }
6:  $\mathcal{S}_{new} \leftarrow \mathcal{S}_{old}$ 
7: for all  $d \in \text{Set of Direct Descendant Nodes of } u$  do
8:    $A_d \leftarrow$  Set of queries at  $u$  for all configurations in  $V_k \times V_l$ 
9:    $\mathcal{S}_{new} \leftarrow \mathcal{S}_{new} \cup A_d$ 
10: /* Remove Bad Actions */
11: /* Find maximum lower bound on gain over all actions in  $\mathcal{S}_{new}$  */
12:  $thres \leftarrow \max_{\alpha' \in \mathcal{S}_{new}} (r(\alpha') - \sigma(\alpha'))$ 
13:  $\mathcal{B} \leftarrow$  All actions  $a$  in  $\mathcal{S}_{new}$  with  $r(\alpha) + \sigma(\alpha) < thres$ 
14:  $\mathcal{S}_{new} \leftarrow \mathcal{S}_{new} \setminus \mathcal{B}$ 
15: return  $\mathcal{S}_{new}$ 

```

5. EXPERIMENTAL EVALUATION

In this section we present an empirical evaluation of our proposed algorithmic framework. The main questions we seek to address are: (1) how the proposed querying policy algorithm compares against baselines for maximizing the number of extracted entities under a specific budget, (2) how the different gain estimators presented in Section 3 compare with each other, and (3) how the proposed querying policy algorithm exploits the structure of the input domain to construct the set of available actions.

We empirically study these questions using both real and synthetic datasets. First, we discuss the experimental methodology, and then we describe the data and results that demonstrate the effectiveness of our framework on crowdsourced entity extraction.

The evaluation is performed on an Intel(R) Cored(TM) i7 3.7 GHz 32GB machine; all algorithms are implemented in Python 2.7.

Gain Estimators: We evaluate the following gain estimators:

- **Chao92Shen:** This estimator combines the methodology proposed by Chao [6] for estimating the number of unseen species with Shen’s formula, i.e., Equation (1). This estimator was also used by Trushkowsky et al. [31].
- **HwangShen:** This estimator combines the regression based approach proposed by Hwang and Shen [13] for estimating the number of unseen species with Shen’s formula.
- **NewRegr:** This estimator corresponds to the new regression based technique proposed in Section 3.3.

All estimators were coupled with bootstrapping to estimate their variance to retrieve an upper bound on the return of a query as shown in Equation (16).

Entity Extraction Algorithms: We evaluate the following algorithms for crowdsourced entity extraction:

- **Rand:** This algorithm executes random queries until all the available budget is used. It selects a random node from the input poset \mathcal{H}_D and a random query configuration $q(k, l)$ from a list of pre-specified k, l value combinations. We expect Rand to be effective for extracting entities in small and dense data domains that do not have many sparsely populated nodes.
- **RandL:** This algorithm executes random queries *only at the lowest level nodes* (i.e., leaf nodes) of the input poset \mathcal{H}_D until all the available budget is used. It selects a random leaf node and a random query configuration $q(k, l)$ from a list of pre-specified k, l value combinations. We expect RandL to be effective for *shallow* data domains when the majority of nodes corresponds to leaf nodes. And similar to Rand, the performance of RandL is expected to be reasonable for small and dense data domains without sparsely populated nodes.
- **BFS:** This algorithm performs a breadth-first traversal of the input poset \mathcal{H}_D , executing one query at each node. The query configuration is randomly selected from a list of pre-specified k, l value combinations. This algorithm promotes exploration of the action space when extracting entities. It also takes into account the structure of the input domain but is agnostic to sparsely populated nodes of the input \mathcal{H}_D .
- **GSChao, GSHWang, GSNewR:** These algorithms correspond to our proposed querying policy algorithm (Section 4.2) coupled with Chao92Shen, HwangShen and NewRegr respectively.
- **GSExact:** This algorithm is used as a near-optimal, omniscient baseline that allows us to see how far off our algorithms are from an algorithm with perfect information. In particular, we combine the algorithm proposed in Section 4.2 with an exact computation of the return or gains from queries. More precisely, the algorithm proceeds as follows: At each round we speculatively execute each of the available actions (i.e., all query configurations across all nodes) and select the one that results in the largest number of return to cost ratio. Since the return of each query is known, the algorithm is not coupled with any of the aforementioned estimators.

Rand, RandL and BFS promote the exploration of the action space when extracting entities, while the other algorithms balance exploration with exploitation. For the results reported below, we run each algorithm ten times and report the average gain achieved under the given budget.

Querying Interface: For all datasets we consider generalized queries

$q(k, l)$ of the type “Give me k more entities that satisfy certain conditions and are not present in an exclude list of size l ”. The conditions correspond to matching the attribute values associated with a node from the input poset. The configurations considered for (k, l) are $\{(5, 0), (10, 0), (20, 0), (5, 2), (10, 5), (20, 5), (20, 10)\}$. Larger values of k or l were deemed unreasonable for crowdsourced queries. The gain of a query is computed as the number of new entities extracted. The cost of each query is computed using an additive model comprised by three partial cost terms that depend on the characteristics of the query.

The three partial cost terms are: (i) **CostK** that depends on the number of responses k requested from a user, (ii) **CostL** that depends on the size of the exclude list l used in the query, and (iii) **CostSpec** that depends on the *specificity* of the query q_s , e.g., we assume that queries that require users to provide more specialized entities such as a “Give me one concert for New York on the 17th of Nov” cost more than more generic queries such as “Give me one concert in New York”. More formally, we define the specificity of a query to be equal to the number on attributes assigned non-wildcard values for the node $u \in \mathcal{H}_D$ the query corresponds to.

For each of the cost terms we assume a maximum cost of \$1 realized by considering the maximum value of the corresponding input variable. The overall cost for a query $q(k, l)$ with specificity s is computed as:

$$Cost(q) = \alpha \cdot \frac{k}{\text{max. query size}} + \beta \cdot \frac{l}{\text{max. ex. list size}} + \gamma \cdot \frac{s}{\text{max. specificity}}$$

The cost of a query should be significantly increased when an exclude list is used, thus we require that β is set to a larger value than α and γ . For the results reported below, we set $\alpha = \gamma = 1$ and $\beta = 5$. Similar results were observed for other settings but are omitted due to space limitations.

5.1 Synthetic Data Experiments

First, we evaluate the proposed framework on extracting entities from a large domain. We consider the event dataset collected from Eventbrite. As described in Section 1, the poset corresponding to the Eventbrite domain contains 8,508,160 nodes with 57,805 distinct events overall. However, only 175,068 nodes are populated leading to an rather sparsely populated domain. Due to lack of popularity proxies for the extracted events, we assigned a random *popularity value* in $(0, 10]$ to each event. These weights are used during sampling to form the actual popularity distribution characterizing the population of each node in the poset.

Results: We evaluate the performance, in terms of number of entities extracted, for the different extraction algorithms described above, across a range of different budgets. We run each algorithm ten times and report the average number of unique events extracted as well as the corresponding standard error. The results are shown in Figure 7. As can be seen, all of our proposed algorithms, i.e., GSChao, GSHWang, GSNewR outperform the baselines under consideration exhibiting an improvement of at least 2X on the total number of unique events extracted. For example, for budget = \$50, our schemes all extracted greater than 500 events while Rand and RandL extracted 1.1 and 0.2 events and BFS extracted 207.7 events, an improvement of over 140%. Moreover, for smaller budgets we observe that these algorithms perform comparably to GSExact that has “perfect information” to the gain of each query, typically giving half the number of entities that GSExact extracts. Note that our estimators have access to few samples and sparse information; the fact that we are able to get this close to GSExact is notable.

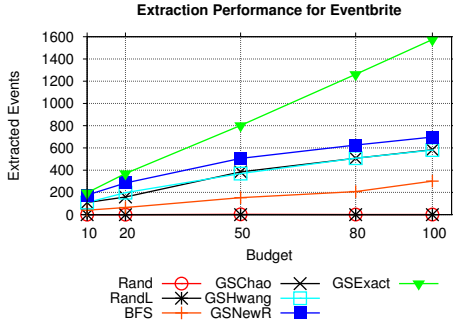

Figure 7: The number of events extracted by different algorithms for the Eventbrite data domain and different budgets.

Table 1: Average absolute relative error for estimating the gain of different queries for Eventbrite.

Q. Size k	EL. Size l	Chao92Shen	HwangShen	NewRegr
5	0	0.470	0.500	0.427
5	2	0.554	0.612	0.567
10	0	0.569	0.592	0.544
10	5	0.580	0.696	0.559
20	0	0.642	0.756	0.601
20	5	0.510	0.60	0.519
20	10	0.653	0.756	0.631

The poor performance of Rand and RandL is due to the sparsity of the Eventbrite data domain. Regarding BFS, we see that it exhibits better performance than Rand and RandL by exploiting the structure of the underlying domain. However, since BFS is agnostic to the cost of the issued queries as well as to sparsely populated areas of the underlying poset, it can only extract a limited number of events. On the other hand, our proposed techniques were able to extract significantly more tuples as they both exploit the structure of the poset and optimize for the cost of the issued queries. Finally, we point out that GSNewR that combines the proposed poset traversal algorithm with our new regression-based gain estimator was able to outperform GSChao and GSHwang.

To further understand the relative performance of GSChao, GSHwang and GSNewR, we evaluate the performance of the gain estimators described above at predicting the number of new retrieved events for different query configurations. We choose ten random nodes from Eventbrite each containing more than 5,000 events. For each of the nodes and each of the available query parameter configurations (k, l) , we execute ten queries of the form “Give me k items from node $u \in \mathcal{H}_D$ that are not included in an exclude list of size l ”. As mentioned in Section 3.2 the exclude list for each query is constructed following a randomized approach.

We measure the performance of each estimator by considering the absolute relative error between the predicted return and the actual return of the query. In Table 1, we report the relative error for each of the three estimators averaged over all points under consideration. As shown, all three estimators perform equivalently with the new regression based technique slightly outperforming Chao92Shen and HwangShen for certain types of queries. For example, for $k = 10, l = 5$, Chao92Shen has a relative error of 0.58, HwangShen had a relative error of 0.7, and NewRegr had a relative error of 0.56. We attribute the improved extraction performance of GSNewR to these improved estimates. The relatively large values for relative errors are justified as the retrieved samples correspond to a very small portion of the underlying population for each of the points. This is a well-known behavior for non-parametric estimators and studied extensively in the species estimation literature [13].

Table 2: The population characteristics for the People’s data.

Person Type	People	News Portal	People
Industry People	743	WSJ	594
Athletes	743	WashPost	597
Politicians	748	NY Times	595
Actors/Singers	744	HuffPost	599
		USA Today	593

5.2 Real Data Experiments

Since the performance of the baseline algorithms is significantly affected by the sparsity of the Eventbrite data domain, we choose to further evaluate the performance of the extraction algorithms for a more dense domain, that we constructed ourselves. We used Amazon’s Mechanical Turk [1] to collect a real-world dataset, targeted at extracting “people in the news”.

We asked workers to extract the names of people belonging to four different types from five different news portals. The people types we considered are “Politicians”, “Athletes”, “Actors/Singers” and “Industry People”. The news portals we considered are “New York Times”, “Huffington Post”, “Washington Post”, “USA Today” and “The Wall Street Journal”. This data domain, referred to as the People’s domain, is essentially characterized by the type of the individual and the news portal. Workers were paid \$0.20 per HIT. We issued 20 HITS for each leaf node of the domain’s poset, resulting in 600 HITS in total. After manually curating name misspellings, we extracted 1,245 unique people in total. Table 2 shows the number of distinct entities for the different values of the people-type and news portal attributes. Finally, the popularity value of each extracted entity was assigned to be equal to the number of times it appeared in the extraction result. The values are normalized during sampling time to form a proper popularity distribution. Collecting a large amount of data in advance from Mechanical Turk and then simulating the responses of human workers by revealing portions of this dataset allows us to compare different algorithms on an equal footing; this approach is often adopted in the evaluation of crowdsourcing algorithms [22, 19, 31].

Results: We first evaluate the performance of the different extraction algorithms. Similarly to Eventbrite we run each algorithm ten times and report the average performance. The results are shown in Figure 8. As shown our proposed techniques (i.e., GSChao, GSHwang and GSNewR) still outperform Rand, RandL and BFS. However, we see that the performance improvement compared to the baselines is smaller compared to Eventbrite. The reason is that the input domain is dense and all nodes of the input poset are populated, so even random techniques may “get lucky” fairly often. Even so, the number of nodes extracted by all our proposed techniques is typically 100% greater than that of the other techniques for small budgets and 54% for larger ones.

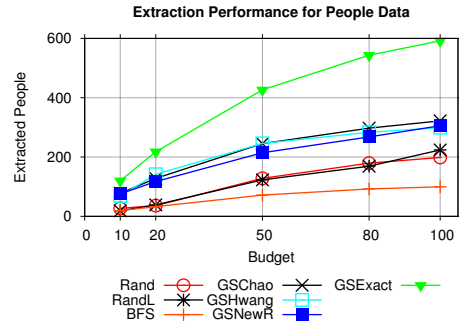

Figure 8: The number of people extracted by different algorithms for the People data domain and different budgets.

We also observe that issuing random extraction queries at the

nodes of the poset outperforms BFS for a significant margin as the available budget increases. This behavior is expected in dense small domains where all the available nodes are populated. Notice that this approach corresponds to a querying policy that focuses purely on exploring different queries. However, exploiting previously obtained information and balancing exploration and exploitation of the possible actions (i.e., following the proposed poset traversal algorithm) leads to superior performance. We further notice that GSChao does better than GSNewR in this case, unlike the previous case. This is because the Chao92Shen estimator performs better when the retrieved samples correspond to a larger portion of the underlying population (i.e., when operating under a large budget), as we see below.

Next, we evaluate the performance of the gain estimators. As before, we issue ten queries to different nodes of the input poset for all available query configurations. Since the input poset is small, we issued ten queries over all nodes. For each gain estimator and query configuration, we computed the average relative error, comparing the estimated query return with the actual query return. The results are shown in Table 3. Again, we observe that for smaller query sizes the regression technique proposed in this paper offers better gain estimates. However, as the query size increases, and hence, a larger portion of the underlying population is observed Chao92Shen outperforms both regression based techniques. Thus, we are able to explain the performance difference between GSChao and the other two algorithms.

Table 3: Average absolute percentage error for estimating the gain of different queries for the People’s data domain.

Q. Size k	EL. Size l	Chao92Shen	HwangShen	NewRegr
5	0	0.295	0.299	0.228
5	2	0.163	0.156	0.144
10	0	0.306	0.305	0.277
10	5	0.341	0.349	0.293
20	0	0.359	0.371	0.467
20	5	0.402	0.418	0.493
20	10	0.405	0.428	0.638

We next explore how our different algorithms traverse the poset, and how they use different query configurations. The results reported are averaged over ten runs. We begin by considering how many queries these algorithms issue at various levels of the poset. In Figure 9, we plot the different number of queries issued at various levels by our algorithms when the budget is set to 10 and 100 respectively. Given a small budget, we observe that all algorithms prefer issuing queries at higher levels of the poset. Notice that inner nodes of the poset are preferred and only a small number of queries is issued at the root (i.e., level one) of the poset. This behavior is justified if we consider that due to their popularity, certain entities are repeatedly extracted, thus leading to a lower gain. As the budget increases, we see that all algorithms tend to consider more specialized queries at deeper levels of the poset. It is interesting to observe that all of our algorithms issue the majority of their queries at the level two nodes, while GSEExact, which has perfect information, focuses mostly on the leaf nodes. Thus, in this case, our techniques could benefit from being more aggressive at traversing the poset and reaching deeper levels; overall, our techniques may end up being more conservative in order to cater to a larger space of posets and popularity distributions. In Figure 10, we plot the different query configurations chosen by our algorithms when the budget is set to 10 and 100 respectively. We observe that GSEExact always prefers queries with $k = 20$ and $l = 0$ for both small and large budgets. On the other hand, our algorithms issue more queries of smaller size when operating under a limited budget and prefer queries of larger size for larger budgets. Out of all algo-

gorithms we see that GSNewR was the only one issuing queries with exclude lists of different sizes, thus exploiting the rich diversity of query interfaces. However, the number of such queries is limited.

Figure 9: The number of queries issued at different levels used when budget is set at 10 or 100.

Figure 10: The different query configurations used when budget is set at 10 or 100.

5.3 Take-Away Points

We have the following recommendations based our results:

- Exploiting the structure of the input domain is effective for maximizing the total number of extracted entities. Also, balancing the exploration of queries for non-observed nodes of the poset with queries over observed nodes of the poset is crucial.
- For sparse domains, e.g., domain specified by large posets with a small number of populated nodes, one should resort to regression based techniques for estimating the expected gain of further queries as they result in better performance. However, for dense domains the Chao92Shen estimator results in better performance as a larger portion of the underlying population can be sampled. The size of the input domain and its sparsity are known in advance to the designer of the querying interface.
- For small budgets the proposed estimator-based poset traversal algorithms (i.e., GSChao, GSHwang and GSNewR) exhibit comparable performance with a traversal algorithm that has oracle access to the gain of each query to be issued. For larger budgets we observe that our algorithms are at most 2.2x away from this adaptive querying strategy with perfect information.

6. RELATED WORK

The prior work related to the techniques proposed in this paper can be placed in a few categories; we describe each of them in turn:

Crowd Algorithms: There has been a significant amount of work on designing algorithms where the unit operations (e.g., comparisons, predicate evaluations, and so on) are performed by human workers, including common database primitives such as filter [21], join [18] and max [10], machine learning primitives such as entity resolution [5, 33] and clustering [25], as well as data mining primitives [3, 29].

Previous work on the task of crowdsourced extraction or enumeration, i.e., populating a database with entities using the crowd [24, 31] is the most related to ours. In both cases, the focus is on a single entity extraction query; extracting entities from large and diverse data domains is not considered. Moreover, the proposed techniques do not support dynamic adaptation of the queries issued against the crowd to optimize for a specified monetary budget.

Knowledge Acquisition Systems: Recent work has also considered the problem of using crowdsourcing within knowledge acquisition systems [15, 17, 34]. This line of work suggests using the crowd for curating knowledge bases (e.g., assessing the validity of the extracted facts) and for gathering additional information to be added to the knowledge base (e.g., missing attributes of an entity or relationships between entities), instead of augmenting the set of entities themselves. As a result, these papers are solving an orthogonal problem. The techniques described in this paper for estimating the amount of information from a query and devising querying strategies to maximize the amount of extracted information will surely be beneficial for knowledge extraction systems as well.

Deep Web Crawling: A different line of work has focused on data extraction from the deep web [16, 28]. In such scenarios, data is obtained by querying a form-based interface over a hidden database and extracting results from the resulting dynamically-generated answer (often a list of entities). Typically, such interfaces provide partial list of matching entities to issued queries; the list is usually limited to the top-k tuples based on an unknown ranking function. Sheng et al. [28] provide near-optimal algorithms that exploit the exposed structure of the underlying domain to extract all the tuples present in the hidden database under consideration. Our work is similar to this work in that our goal is to also extract entities via a collection of interfaces (in our case the interfaces correspond to queries asked to the crowd).

The main difference between this line of work and ours is that answers from a hidden database are deterministic, i.e., a query in their setting will always retrieve the same top-k tuples. This assumption does not hold in the crowdsourcing scenario considered in this paper and thus the proposed techniques are not applicable. In their setting, it suffices to ask each query precisely once. In our setting, since crowdsourced entity extraction queries can be viewed as random samples from an unknown distribution, one needs to make use of the query result estimation techniques introduced in Section 3.

7. CONCLUSIONS AND FUTURE WORK

In this paper, we studied the problem of crowdsourced entity extraction over large and diverse data domains. We introduced a novel crowdsourced entity extraction framework that combines statistical techniques with an adaptive optimization algorithm to maximize the total number of unique entities extracted. We proposed a new regression-based technique for estimating the gain of further querying when the number of retrieved entities is small with respect to the total size of the underlying population. We also introduced a new algorithm that exploits the often known structure of the underlying data domain to devise adaptive querying strategies. Our experimental results show that our techniques extract up to 3.3X more entities compared to a collection of baselines, and are at most 2.2X away from an omniscient adaptive querying strategy with perfect information.

Some of the future directions for extending this work include reasoning about the quality and correctness of the extracted result as well as extending the proposed techniques to other types of information extraction tasks. As mentioned before, the techniques proposed in this paper do not deal with incomplete and imprecise information. However, there has been an increasing amount of literature on addressing these quality issues in crowdsourcing [7, 14, 20, 32]. Combining these techniques, or entity resolution techniques [33] that reason about similarity of extracted entities, with our proposed framework is a promising future direction. Finally, it is of particular interest to consider how the proposed framework can be applied to other budget sensitive information extraction applications including discovering valuable data sources for integration tasks [26] or curating and completing a knowledge base [17].
